Abstract

It is shown that the linear resistivity dependence on temperature for metals above the Debye's temperature mainly is caused by electron-electron scattering of randomly moving electrons. The electron mean free path in metals at this temperature range is in inverse proportion to the effective density of randomly moving electrons, *i.e.* it is in inverse proportion both to the temperature, and to the density-of-states at the Fermi surface. The general relationships for estimation of the average diffusion coefficient, the average velocity, mean free length and average relaxation time of randomly moving electrons at the Fermi surface at temperatures above the Debye's temperature are presented. The effective electron scattering cross-sections for different metals also are estimated. The calculation results of resistivity dependence on temperature in the range of temperature from 1 K to 900 K for Au, Cu, Mo, and Al also are presented and compared with the experimental data. Additionally in temperature range from 1 K to 900 K for copper, the temperature dependences of the mean free path, average diffusion coefficient, average drift mobility, average Hall mobility, average relaxation time of randomly moving electrons, and their resultant phonon mediated scattering cross-section are presented.

Keywords

Effective Density of Randomly Moving Electrons, Electron-Electron Scattering, Electron Diffusion Coefficient, Electron Mean Free Path, Scattering Cross-Section

1. Introduction

The foundations of the electron theory of metals were laid on the proposition of free electrons which are assumed to be of the same order of valence electrons per

unit volume. In order to obtain the correct order of the magnitude for conductivity and correct temperature variation of the mean free path of electrons at room temperature range, it was assumed that electron mean path is caused by thermal vibrations of lattice [1]. On the other hand, it is well known that electrons obey the Pauli principle and that electrons are described by the Fermi-Dirac statistics. The latter statistics let to explain the experimental results of the electron heat capacity of metals: Why metals and insulators have around the same heat capacity. The resolution of this paradox is one of the greatest successes of the Sommerfeld's model [2]. Considering this model the main conclusion has been done that only a small part of electrons with energy close to the Fermi level energy can randomly move, and that electrons which energy is well below the Fermi level cannot change their energy because all neighbor levels are occupied. The main weakness of the Sommerfeld's model is that the effective density of randomly moving electrons was not properly defined which can be scattered affected by external fields. So, the total density of valence electrons n traditionally used for description of the electrical conductivity of the metals is unacceptable. Concerning that the Sommerfeld's model is based on the spherical Fermi surface, there also are uncertainties in determination of both the density-of-states (DOS) in conduction band at the Fermi energy E_F , and the Fermi energy, because the Fermi surfaces for many of metals are not spherical [3]. The adequate definition for the effective density n_{eff} of the randomly moving electrons in metals is presented in [4] [5].

This study mainly is addressed to using the stochastic description of the effective density of randomly moving electrons to investigation of the electron scattering mechanism at temperatures above the Debye's temperature. Additionally we estimated the resistivity dependence on temperature for Au, Cu, Mo, and Al in the temperature range from 1 K to 900 K. The mentioned problems are very important in solid state physics for relevant understanding and description of kinetic phenomena in metals, and semiconductors with highly degenerate electron gas.

2. Results and Discussions

2.1. Basic Properties of Randomly Moving Electrons

It is well known that the Fermi distribution function $f(E)$ for electrons is expressed as

$$f(E) = 1 / [1 + \exp(E - \eta) / kT]. \quad (1)$$

It specifies a probability that a level with the energy E on average is occupied by an electron. Here, E is the electron energy; η is the chemical potential; k is the Boltzmann's constant, and T is the absolute temperature. Considering that the difference between the chemical potential and Fermi energy E_F is only about 0.01% for room temperature [2], further for calculation we use the Fermi distribution function in the following form:

$$f(E) = 1 / [1 + \exp(E - E_F) / kT]. \quad (2)$$

Thus, the total density of the free valence electrons n in conduction band is described by an integral on the density-of-states $g(E)$ as

$$n = \int_0^{\infty} g(E) f(E) dE. \quad (3)$$

The electrical conductivity depends not only on the density-of-states $g(E)$ in conduction band and Fermi distribution function $f(E)$, but it also depends on the probability $f_1(E) = 1 - f(E)$ that any electron with the definite energy E at a given temperature T can be thermally scattered or can change his energy under influence of the external fields. Thus, the effective density of electrons n_{eff} which take part in random motion and in conductivity is described by the probability

$$h(E) = f(E) [1 - f(E)]. \quad (4)$$

Therefore, the effective density of randomly moving electrons n_{eff} is described as [4] [5]

$$n_{\text{eff}} = \int_0^{\infty} g(E) f(E) [1 - f(E)] dE = kT \int_0^{\infty} g(E) (-\partial f(E)/\partial E) dE. \quad (5)$$

From this expression follows that the term $(-\partial f(E)/\partial E)$ is the probability density function $p(E)$ that electron with energy E is available to change his energy due to thermal and electrical influence:

$$p(E) = (-\partial f(E)/\partial E) = h(E)/kT, \quad (6)$$

and the integral probability distribution function is

$$F(E) = \int_0^E p(E_1) dE_1 = 1 - f(E). \quad (7)$$

The functions $p(E)$ and $F(E)$ meet the requirements of the probability theory. The probability density dependence on energy of randomly moving electrons is presented in **Figure 1**. The area restricted by dash-line is equal to 1, and the effective width of the probability density function in energy is $\Delta E_{\text{eff}} = 4kT$. Thus, the density of randomly moving electrons are described by probability density function $p(E)$, while the total density of the free electrons is constant quantity defined by the sum of valence electron density. The determination of the effective density of randomly moving electrons in homogeneous materials by Equation (5) is valid in all cases: with non-degenerate and with degenerate electron gas. For materials with non-degenerate electron gas the probability $[1 - f(E)] \approx 1$ because $f(E) \ll 1$, and, therefore, all electrons in conduction band n take part in random motion, and their density can be described as

$$n_{\text{eff}} = n = \int_0^{\infty} g(E) f(E) dE. \quad (8)$$

This is the case when the classical statistics is applicable. In the case of highly degenerate electron gas, and considering that probability density function $(-\partial f(E)/\partial E)$ has a sharp maximum at $E = E_F$, the Equation (5) can be presented in the following form:

Figure 1. The probability density $p(E)$ dependence on energy E of randomly moving electrons near the Fermi energy $E_F = 2$ eV at $T = 295$ K.

$$n_{\text{eff}} = g(E_F)kT \ll n, \tag{9}$$

where $g(E_F) = g(E)$ at $E = E_F$. The density-of-states (DOS) at Fermi energy $g(E_F)$ can be obtained from the experimental results of the electron heat capacity measurements [6]:

$$c_V = (\pi^2/3)g(E_F)k^2T = \gamma T. \tag{10}$$

Now we estimate the energy fluctuation of randomly moving electrons on the Fermi surface:

$$\langle (E - \langle E \rangle)^2 \rangle = \langle (E - E_F)^2 \rangle = \int_0^\infty (E - E_F)^2 g(E) f(E) [1 - f(E)] dE, \tag{11}$$

or

$$\begin{aligned} \langle (E - \langle E \rangle)^2 \rangle &= g(E_F)(kT)^3 \int_0^\infty (\varepsilon - \varepsilon_F)^2 f(\varepsilon) [1 - f(\varepsilon)] d\varepsilon \\ &\cong 3.2899 g(E_F)(kT)^3 \cong \frac{\pi^2}{3} g(E_F)(kT)^3 \end{aligned} \tag{12}$$

From Equations (10) and (12) follows that

$$\langle (E - \langle E \rangle)^2 \rangle = kT^2 c_V. \tag{13}$$

It is in accordance with the theory of energy fluctuation of free randomly moving particles [7]. This result shows that electron scattering is inelastic process.

The volume for one of randomly moving electron with the Fermi velocity for different metals can be estimated as:

$$V_{\text{el}} = 1/n_{\text{eff}} = 1/[g(E_F)kT], \tag{14}$$

This volume increases with temperature decrease as $1/T$.

For metals and other materials with highly degenerate electron gas the effective density of scattered electrons is described by Equation (9), and it is proportional to temperature. The DOS $g(E_F)$ for various metals are presented in **Figure**

2 (the values of the parameter γ were taken from [6]). In the same figure there are presented the effective densities of randomly moving electrons $n_{\text{eff}} = g(E_F)kT$ at $T = 295$ K. According to the Sommerfeld's model based on the spherical Fermi surface the DOS $g(E_F)$ for metals is described as [2]

$$g(E_F) = \frac{m^* (3n)^{1/3}}{\pi^{4/3} \hbar^2}, \quad (15)$$

where m^* is the effective mass of the electron, and $\hbar = h/2\pi$ is the Plank's constant. This relation is presented in **Figure 2** by solid line. This relation nearly describes the experimental results of $g(E_F)$ for some of alkali and noble metals, but for other metals there are very large differences. Considering that energy structures of DOS for many metals are composite [3], there is no definite relation between the Fermi energy E_F and the total density of free electrons n , and also due to the same reason there is no definite relation between the Fermi energy E_F and the density-of-states at the Fermi surface.

2.2. Conductivity and Diffusion Coefficient of Randomly Moving Electrons in Metals

The electric conductivity σ of the homogeneous materials and diffusion coefficient D of randomly moving carriers can be described by such general expression [8] [9]:

$$\sigma = q^2 D \left(\frac{\partial n}{\partial \eta} \right)_T. \quad (16)$$

After simple calculation ones obtain [4] [5]:

$$\sigma = q^2 D \int_0^\infty g(E) f(E) [1 - f(E)] dE = \frac{q^2 D}{kT} n_{\text{eff}} = q \mu_{\text{drift}} n_{\text{eff}}, \quad (17)$$

where μ_{drift} is drift mobility of randomly moving charge carriers. These relations are valid for all homogeneous materials with a single type of charge carriers at any their degeneracy degree and it confirms that the electric conductivity for metals is determined by the effective density of randomly moving charge carriers, but not by the total density of free charge carriers. The distribution of experimental values of electric conductivity [6] for different metals on DOS at the Fermi surface at $T = 295$ K is presented in **Figure 3(a)**.

For metals the Equation (17) can be rewritten as

$$\sigma = q^2 g(E_F) D = (1/3) q^2 g(E_F) v_F^2 \tau_F, \quad (18)$$

This expression is well known for metals, and it also can be obtained by solving Boltzmann's kinetic equation [10] [11]. The distribution of the diffusion coefficient D of randomly moving electrons dependence on DOS for various metals is presented in **Figure 3(b)**. It is interesting to note that electric conductivity for metals (**Figure 3(a)**) on average decreases with increasing of the density-of-states at the Fermi surface, *i.e.* with increasing of the effective density of randomly moving electrons. A spread of electric conductivity values in this fig-

ure is completely caused by the spread of diffusion coefficient values as shown in **Figure 3(b)**. A tendency of conductivity decrease as $1/g^{1/2}(E_F)$ (**Figure 3(a)**) is caused by diffusion coefficient tendency to decrease as $1/g^{3/2}(E_F)$ (**Figure 3(b)**).

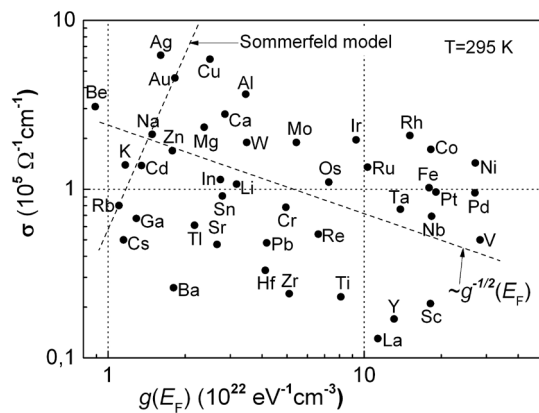

Figure 2. The effective density of randomly moving electrons n_{eff} for different metals at $T = 295$ K (the left scale), and the density-of-states at Fermi surface $g(E_F)$ (the right scale is selected in accordance to the left scale that positions of dots in the pattern were the same for both scales); the solid line represents the DOS $g(E_F)$ for Sommerfeld’s model.

(a)

(b)

Figure 3. (a) Distribution of experimental values of electric conductivity σ [6], and (b) diffusion coefficient D of the randomly moving electrons for different metals on DOS at the Fermi surface at $T = 295$ K. D has been evaluated from Equation (18).

From Equation (18) follows that diffusion coefficient of randomly moving electrons is related minimum with the five transport parameters of randomly moving electrons:

$$D = \frac{\sigma}{q^2 g(E_F)} = \frac{1}{3} v_F^2 \tau_F = \frac{1}{3} l_F v_F, \quad (19)$$

where $l_F = v_F \tau_F$ is the mean free path of the electrons at the Fermi surface. What parameters mostly cause the spread of diffusion coefficient of electrons on density-of-states for metals at $E = E_F$?

2.3. The Mean Free Path of Randomly Moving Electrons in Metals at Temperatures above the Debye's Temperature

The very important parameter characterizing the scattering mechanism of randomly moving charge carriers is their mean free path. In the case of electron-phonon scattering mechanism, the cross-section of scattering $\sigma_{\text{el-ph}}$ increases with temperature due to lattice ions vibration amplitude increasing [6] [8] [10]. It is interesting to find the relation of the mean free path of randomly moving electrons with their effective scattering cross-section σ_{eff} . According to [6], the electron-electron scattering cross-section accounting the screening effect is about 10^{-15} cm^2 . All randomly moving electrons n_{eff} with the average Fermi velocity v_F are scattered. Then the mean free path of scattered electrons in metals can be described as [6]

$$l_F = v_F \tau_F = 1/(\sigma_{\text{eff}} n_{\text{eff}}) = 1/[\sigma_{\text{eff}} g(E_F) kT], \quad (20)$$

and the average relaxation time as

$$\tau_F = 1/(\sigma_{\text{eff}} n_{\text{eff}} v_F) = 1/(\sigma_{\text{eff}} g(E_F) v_F kT). \quad (21)$$

There it must be pointed that effective electron scattering cross-section σ_{eff} doesn't depend on temperature at temperatures above the Debye's temperature. So, the statement that scattering cross-section at this temperature range is proportional to temperature contradicts to experimental resistivity data of metals. The Equation (20) directly shows that electron mean free path is in inverse proportion not only to temperature, but also to density-of-states at the Fermi surface. Besides the product $l_F \sigma_{\text{eff}} = 1/n_{\text{eff}} = V_{\text{el}}$ (here V_{el} is the volume for one randomly moving electron (Equation (15)). Considering that $D = (1/3) l_F v_F \sim 1/g^{3/2}(E_F)$, and $l_F \sim 1/g(E_F)$, it means that electron Fermi velocity $v_F \sim 1/g^{1/2}(E_F)$, *i.e.* electron velocity at Fermi surface on average decreases with density-of-states increasing.

In paper [12], there are presented the calculation data of electron mean free path for large group of metals. It is interesting to find a relation between the mean free paths and diffusion coefficients of electrons. This relationship for a group of metals is presented in **Figure 4**. The relationship between the mean free path and the diffusion coefficient of randomly moving electrons in metals in the linear resistivity dependence on temperature range can be approximated as

Figure 4. Relationship between the mean free path l_F and the diffusion coefficient D of electrons for a group metals at room temperature ($T_0 = 295$ K; • – solid dots l_F from [12]; ○ – open dots l_F from dimension effect [13]; half filled dots – both data coincide).

$$l_F(T) = 1.39(D(T_0))^{2/3} (T_0/T), \tag{22}$$

here l_F is in nm, and $D(T_0)$ is in cm^2/s at $T_0 = 295$ K. A small spread of the data in **Figure 4** from Equation (22) may be originated from some uncertainty of estimation of the mean free path values due to a very complicate structure of the Fermi surfaces especially of the transient group metals. Some different values of the electron mean free path were obtained by other authors [14] [15]: the estimated l_F for Cu is 55 nm, for Al is 22 nm, and for W is 19.1 nm, while for the same metals in the paper [12], respectively, there are such data: 39.9 nm, 18.9 nm, and 15.5 nm.

From Equation (20) the effective electron-electron scattering cross-section can be estimated as

$$\sigma_{\text{eff}} = 1/(l_F n_{\text{eff}}) = 1/[l_F g(E_F) kT]. \tag{23}$$

The effective electron scattering cross-sections are distributed in the range $(0.40 - 3.6) \cdot 10^{-15} \text{ cm}^2$, and they do not depend on temperature for that temperature range where the resistivity is proportional to temperature T . The effective electron-electron cross-section for every metal has a particular value, which depends on the Fermi surface structure. Considering that mean free path data for different metals are different due to specific effective electron scattering cross-section values, the spread of those values causes also the spread of both the conductivity (**Figure 3(a)**) and the diffusion coefficient (**Figure 3(b)**) values. From obtained results follows that the resistivity linear dependence on temperature above the Debye temperature Θ_D is caused by the effective randomly moving charge carrier density dependence on temperature.

From Equations (19)-(22) it is possible to design the following important pattern (**Figure 5**) where there are shown the relationships of the mean free path, average velocity, and the average relaxation time of the randomly moving electrons with their diffusion coefficient for different metals at temperature 295 K. The average velocity of electrons at the Fermi surface can be described as

Figure 5. Relationships of the mean free path l_F , average velocity v_F , and average relaxation time τ_F of randomly moving charge carriers with their diffusion coefficient for different metals at $T=295$ K. The data dots for the same metals are connected with vertical dash lines.

$$v_F = 2.165(D(T_0))^{1/3}, \quad (24)$$

where v_F is in units 10^5 m/s and does not depend on temperature, $D(T_0)$ is in cm^2/s at $T_0 = 295$ K, and similarly the average relaxation time of electrons at the Fermi surface in the linear resistivity dependence on temperature range as

$$\tau_F(T) = 0.64(D(T_0))^{1/3} (T_0/T), \quad (25)$$

where τ_F is in units 10^{-14} s, and $D(T_0)$ in cm^2/s at $T_0 = 295$ K.

There must be pointed that statement that average relaxation time for all metals in the range of the linear resistivity dependence on temperature can be expressed as $\tau_F \cong \hbar/kT$ [16] is not right, because the average relaxation times for different metals at room temperature are in the range $(0.6 - 4) \cdot 10^{-14}$ s (Figure 5), while this value according to [16] at $T=295$ K must be about 2.6×10^{-14} s (horizontal dash line in Figure 5).

In the case of electron-phonon scattering the cross-section must increase with temperature increasing [6], and it would originate the resistivity dependence on temperature as T^2 in the range of temperatures above the Debye's temperature, but it does not take place. Heretofore the linear resistivity dependence on temperature was explained by electron-phonon scattering keeping that all valence electrons take part in current transport, but it is inconsistent with the Pauli's principle and Fermi distribution function.

Accounting the real effective density of randomly moving electrons let us to conclude that electron-electron scattering is the main mechanism that causes the linear resistivity dependence on temperature of metals above the Debye's temperature.

2.4. The Phonon-Mediated Correction to the Effective Electron-Electron Scattering Cross-Section

It was shown that the effective electron scattering cross-section σ_{eff} doesn't de-

pend on temperature at temperatures above the Debye temperature, but also it was shown that average electron relaxation time at Fermi surface $\tau_F \sim 1/T$, and mean free path $l_F = v_F \tau_F \sim 1/T$. Considering that at temperatures below the Debye's temperature the resistivity decreases with temperature more steeply than $1/T$, there arise the question: What is the role of phonons? In **Figure 6(a)** there are presented the resistivity of Au, Cu, Mo, and Al experimental dependences on temperature [17]. What effects cause such steep resistivity decreasing with temperature in temperature range below the Debye's temperature \mathcal{O} ?

The independent resistivity part on temperature below 10 K is the residual electric resistivity due to scattering of electrons from chemical and structural imperfections in the investigated samples.

It seems that effective electron scattering cross-section depends on the exchange of thermal energies of lattice and randomly moving electrons, *i.e.* depends on the ratio of the thermal energy of the phonon to thermal energy of the electron. Though the kinetic energy of randomly moving electron is equal to $E_{kl} = mv_F^2/2$, but its thermal energy is only

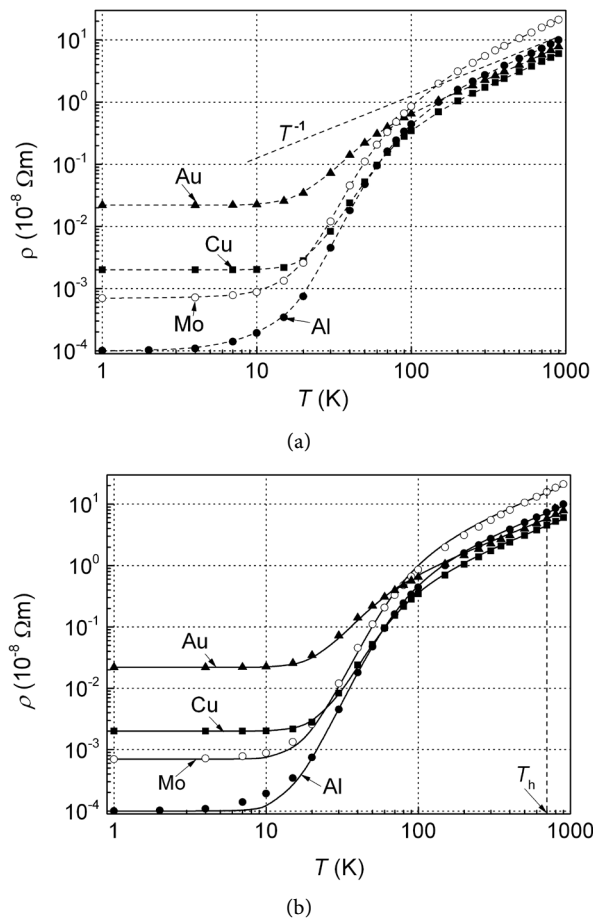

Figure 6. (a) Resistivity ρ dependence on temperature T for Au, Cu, Mo and Al: (a) dots are experimental data taken from [17], dash lines are used only for connections between dots; (b) solid lines are the calculation results from Equation (32); $T_h = 700$ K.; the other parameters used for calculations are listed in **Table 1**.

Table 1. The parameters used for calculation Au, Cu, Mo, and Al resistivity dependencies on temperature.

Metal	$\rho_0, 10^{-8} \Omega\text{m}$ at $T = 1 \text{ K}$	$\rho, 10^{-8} \Omega\text{m}$ at $T_h = 700 \text{ K}$	$v_F, 10^6 \text{ m/s}$	Θ, K used in this work	Θ, K cited in references	$\sigma_{\text{eff}},$ 10^{-15} cm^2
Au	0.0220	5.816	1.16	200	165 [7]; 185 [18]	0.53
Cu	0.0020	4.514	1.14	343	310 [18]; 343 [7]	0.40
Mo	0.00070	15.81	0.603	410	375 [18]; 450 [7]	0.66
Al	0.00010	7.322	0.874	410	380 [18]; 428 [7]	0.50

Note: the resistivities ρ_0 at $T = 1 \text{ K}$, and ρ at $T_h = 700 \text{ K}$ are taken from [17]; v_F is calculated from Equation (24); σ_{eff} is calculated from Equation (23).

$$E_{e1} = (\pi^2/6)(kT)^2 g(E_F)/n_{\text{eff}} = (\pi^2/6)(kT) \approx 1.64kT. \tag{26}$$

The average phonon thermal energy at temperatures over Debye’s temperature Θ is about $3 kT$ [7] [10] because all lattice waves are excited, but in temperature range below temperature Θ only the lattice waves with low frequencies are excited. Accounting that electron scattering process is inelastic, *i.e.* accounting the electron energy fluctuations, which cause the excitation and annihilation of phonons, the average phonon thermal energy can be described as [10]:

$$E_{\text{ph1}} = 3kT \left(\frac{T}{\Theta}\right)^4 \int_0^{\Theta/T} \frac{4x^5}{(e^x - 1)(1 - e^{-x})} dx. \tag{27}$$

Thus, the ratio of the average thermal energies between phonon to electron can be described as

$$\frac{E_{\text{ph1}}}{E_{e1}} = \frac{3kT}{1.64kT} \left(\frac{T}{\Theta}\right)^4 \int_0^{\Theta/T} \frac{4x^5}{(e^x - 1)(1 - e^{-x})} dx \approx 1.83\eta(T/\Theta), \tag{28}$$

where

$$\eta(T/\Theta) = \left(\frac{T}{\Theta}\right)^4 \int_0^{\Theta/T} \frac{4x^5}{(e^x - 1)(1 - e^{-x})} dx \tag{29}$$

is the phonon mediation factor. So, the phonon mediated resultant electron scattering cross-section σ_{res} can be described as

$$\sigma_{\text{res}} = \sigma_{\text{eff}} \eta(T/\Theta). \tag{30}$$

here the quantity σ_{eff} accounts the constant multiplier 1.83, because at $T \gg \Theta$ from Equation (21) we obtain the quantity σ_{eff} independent on T . The resultant average relaxation time τ_{res} is described as

$$\frac{1}{\tau_{\text{res}}} = \frac{1}{\tau_{\text{eff}}} + \frac{1}{\tau_{\text{imp}}}, \tag{31}$$

where $\tau_{\text{eff}} = 1/(\sigma_{\text{res}} n_{\text{eff}} v_F) = 1/(\sigma_{\text{res}} g(E_F) v_F kT)$, and $\tau_{\text{imp}} = 1/(\sigma_{\text{imp}} N_{\text{imp}} v_F)$; σ_{imp} is the average cross-section of the impurity defect, N_{imp} is the impurity density.

The metal resistivity in the overall temperature range can be described as

$$\rho_{\text{res}} = \rho_0 + \rho(T_h) \cdot (T/T_h) \cdot \eta(T/\Theta), \tag{32}$$

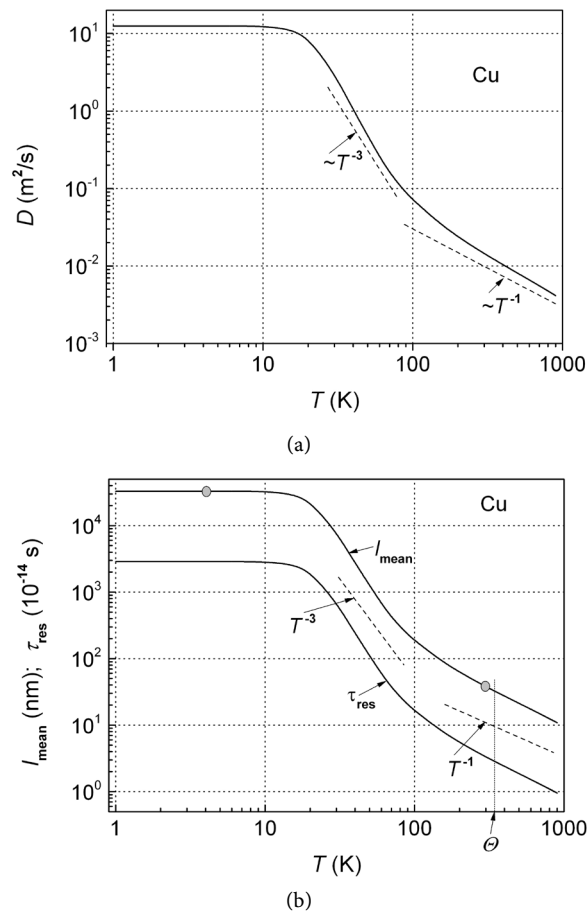

Figure 7. (a) The diffusion coefficient D of randomly moving electrons dependency on temperature T for Cu; (b) the comparison of the mean free path l_{mean} and the resultant electron relaxation time τ_{res} dependencies on temperature T for Cu; dots l_{mean} are estimated from dimension effect [13].

where $T_h \gg \Theta$ is the reference temperature in the high linearity range of the resistivity dependence on temperature (here for calculation we take $T_h = 700$ K). The resistivity dependence on temperature for Au, Cu, Mo and Al are presented in **Figure 6(a)**. The parameters used for calculations are listed in **Table 1**. The Debye's temperature Θ has been chosen to the best agreement between calculation data from Equation (32) and experimental dots (**Figure 6(b)**). It is seen that calculation data sufficiently good agree with experimental results. A small disagreement between calculation and experimental data in particular temperature ranges may be is due to that Debye temperature can change with temperature [7] [18]. Here the calculations have been performed by using constant quantity Θ , which values for calculated resistivities of a few metals are presented in the **Table 1**.

Considering that calculation data by using Equation (32) very well agree to the measurement results for Cu (**Figure 6(b)**), further we present the basic kinetic parameters for copper in temperature range from 1 K to 900 K. In **Figure 7(a)** there is presented the diffusion coefficient of the randomly moving electrons

Figure 8. (a) The phonon mediated resultant electron-electron scattering cross-section σ_{res} dependency on temperature for Cu; (b) the effective density n_{eff} , drift mobility μ_{drift} , and Hall mobility μ_{H} of randomly moving electrons dependencies on temperature for Cu.

dependency on temperature for Cu. The diffusion coefficient has been evaluated from Equation (18). The comparison of the mean free path l_{mean} and the resultant electron relaxation time τ_{res} of the randomly moving electrons dependencies on temperature for Cu in temperature range from 1 K to 900 K is presented in **Figure 7(b)**. The mean free path l_{mean} was evaluated from relation $D = (1/3)l_{\text{mean}}v_{\text{F}}$, and the resultant electron relaxation time τ_{res} was evaluated as $\tau_{\text{res}} = l_{\text{mean}}/v_{\text{F}}$.

The resultant phonon mediated electron-electron scattering cross-section σ_{res} is shown in **Figure 8(a)** at temperature higher than 20 K, because at temperatures lower than 20 K electron scattering cross-section is determined by the neutral impurity atom cross-section. For the most of metals the cross-section is in the range $(0.5 - 1.2) \cdot 10^{-15} \text{ cm}^2$ [18] (here for estimation of impurity density N_{imp} we take $\sigma_{\text{imp}} \approx 0.7 \cdot 10^{-15} \text{ cm}^2$). The effective density n_{eff} , drift mobility μ_{drift} , and Hall mobility μ_{H} of randomly moving electrons dependencies on temperature from 1 K to 900 K are presented in **Figure 8(b)**. It is interesting to note that at temperatures over the Debye temperature the Hall mobility changes as $1/T$, but drift mobility changes as $1/T^2$, and at temperature below 20 K the Hall mobility is constant, but drift mobility changes as $1/T$. Thus, considering that densi-

ty-of-states and velocity of electrons at Fermi surface don't depend on temperature, it is easy from resistivity (conductivity) data to find the basic electron transport characteristics for metals.

3. Conclusions

The investigation results of the fundamental transport characteristics of free electrons on the base of the effective density of randomly moving electrons in metals have been presented. It let to estimate the real average characteristics of randomly moving electrons in metals, such as electron diffusion coefficient, drift mobility, free path, velocity, relaxation time, and to show that these quantities in homogeneous metals above the Debye temperature mainly are due to electron-electron scattering. It is shown that the effective electron scattering cross-section does not depend on temperature in the linear resistivity dependence on temperature range.

The calculation results of resistivity dependence on temperature in the range of temperature from 1 K to 900 K for Au, Cu, Mo, and Al are presented and compared with the experimental data. Additionally for Cu at first time the mean free path, average diffusion coefficient, average drift mobility, average relaxation time of randomly moving electrons dependences on temperature from 1 K to 900 K are presented.
