The evaluation of rheological properties of cement systems is getting more relevant with growing interest to self-consolidating concrete (SCC), high-performance concrete (HPC) and ultrahigh-performance concrete (UHPC). The rheology models are a perspective tool to predict and manage the properties of cement systems in the fresh and hardened state. The current research is focused on the rheological test of cement systems modified by multiwalled carbon nanotubes (MWCNT) dispersion with and without polycarboxylate ether (PCE). The content of dispersion with 1% concentration of MWCNT in cement pastes varied from 0.125 to 0.5% by weight of cement. The dosage of PCE was taken as 0.6% by weight of cement. The cement pastes were prepared based on Portland cement without mineral additives. The rheological test was carried out at 5, 30, 60, and 120 min after mixing of cement paste. The rheological test established that modification of cement pastes by MWCNT dispersion in dosage 0.25% leads to the decrease of yield stress by 30.7% and increase of plastic viscosity by 29.6%. The combined modification by PCE and MWCNT dispersion shows the decrease in plastic viscosity of cement pastes by 9.90% in dosage of MWCNT equal to 0.5% by weight of cement, reduction of water demand by 20% for the same workability, and decrease of yield stress till 0 Pa. It gives the ability to obtain the self-compacting mixtures. The cement pastes with and without MWCNT dispersion revealed the shear-thinning behavior during 120 min after mixing. The modification of cement pastes by PCE with and without MWCNT dispersion showed the shear-thickening behavior which remains during 120 min after mixing.

1. Introduction

The application of rheology models based on the main rheological parameters such as viscosity, shear stress, and thixotropy can provide the ability to predict the properties of designed concrete with relatively high accuracy. This theme is becoming more relevant with growing interest to development of self-consolidating concrete (SCC), high-performance concrete (HPC) and ultrahigh-performance concrete (UHPC), and new technologies of concrete works and new fields of concrete application [1–3]. Some researchers make attempts to deduce the correlation

between fundamental rheological parameters and workability of fresh concrete such as evaluation of flowability, spreadability, pumpability, slump flow, and some others which are determined via standard methods [4, 5].

The dilatancy observed in concrete mixtures is an important phenomenon in their transportation by pumping. The researchers investigate the dilatant behavior of concrete mixtures and explain its appearance due to the increase of system's volume under shear stress during the flow [6].

It should be noted that rheological parameters are usually determined for cement mortars and pastes. Concrete is a multicomponent material; therefore, the evaluation of

rheological properties of concrete requires the corresponding correlation with cement pastes. The study in reference [7] provides the good correlation between mortar and fresh self-compacting concrete as a function of the time and temperature based on the assumption that mortar and concrete are described as Bingham fluids. The properties of fine [8] and coarse aggregates [9] must be taken into account with the purpose of the prediction of rheological properties of concrete mixtures.

The rheology gives the ability to predict and manage by the properties of fresh concrete and mortar, effect on hydration kinetic, performance, and durability of cement composites [10–12]. For example, Kwasny et al. established that the increase in the yield stress value leads to the increase in the total content of the surface air voids in surface finish of cement-based mortars [12].

A number of factors influence on rheological parameters of concrete such as chemical composition and fineness of cement, particle size distribution, and geometrical parameters of solid components [13–15]; properties of filler [16, 17]; water to cement ratio [18], cement hydration, temperature and humidity [19, 20]; parameters of mixing, used equipment for measurements of rheological properties [21, 22]; The rheological parameters of concrete depend on chemical composition and fineness of cement, particle size distribution and geometrical parameters of solid components [13–15], properties of filler [16, 17], water to cement ratio [18], cement hydration, temperature and humidity [19, 20], parameters of mixing and used equipment for rheological test [21, 22], properties of mineral and chemical admixtures [23–26].

The influence of mineral and chemical admixtures on the rheology of fresh concrete and mortars enables to clarify the mechanisms of their actions and make the conclusions about their effectiveness in cement systems. The insight of action mechanism of admixtures is necessary for development of new generation concrete.

Among the mineral additives, the silica fume, metakaolin, granulated blast furnace slag, and fly ash are more widely used for modification of cement composites. Frequently, they are applied as substitution of Portland cement. Ghoddousi et al. studied the influence of packing density of silica fume, metakaolin, and low activity-granulated blast-furnace slag on the rheology of self-consolidating concrete. They established the optimal packing density of about 0.804 for improvement of the rheological properties [27].

Dauksys et al. [6] investigated the dilatancy of cement paste with replacement of cement mass by microsilica. The authors identified that replacement by 9% of microsilica leads to volume change of cement paste from 1.22% to 0% and the reduction of dilatancy.

Reference [28] demonstrates that metakaolin as replacement of 20% cement increased the viscosity of the mixture due to high specific surface and irregular or plate shape of metakaolin particles.

The plasticizing admixtures, as a kind of chemical admixtures, disperse the cement particles and improve the workability of concrete. The better plasticizing effect can be reached with the increase of zeta potential and decrease of surface tension and steric effect, which is determined by molecular parameters of monomers [29]. A number of research

studies are devoted to the investigation of influence of plasticizing admixtures on the rheological properties of cement systems [30, 31]. M.-H. Zhang et al. compared the effect of three types of plasticizers such as lignosulphonate, polycarboxylate, and polynaphthalene, on the loss of workability of cement pastes. They identified that yield stress and effective viscosity are lower for polycarboxylate and polynaphthalene superplasticizers in comparison with lignosulphonate at 30 min [32]. Polycarboxylate ether plasticizers are more commonly used in connection with their action mechanism in cement systems. The decrease of yield stress in cement systems for polycarboxylate plasticizers is caused by the steric effect of action mechanism. At the same time, the increase of viscosity is caused by polymer chains of polycarboxylate plasticizer in the solution, which leads to the cluster formation [33].

Development of nanotechnology promotes the increase of interest in the modification of cement composites by different types of nanostructures. Regardless to the excellent properties of nanostructures and improvement of the performance of cement composites by nanostructures modification in low dosages, their application in construction practice is limited. The limitation of their application is explained by the coagulation processes which take part during the storage in connection with strong van der Waals forces of nanoparticles and nanostructures. The action mechanism of nanoparticles, which is not clear in general, requires further investigations. The studying of rheological behavior of cement systems modified by nanostructures can promote the understanding of this action mechanism and make the prediction about properties of cement composites in the hardened state [34–36].

The authors of research studies [37–39] identified the reduction in the workability and increase in viscosity of cement pastes due to modification by admixtures with progressively finer sizes, such as nanosilica. They emphasized the importance to establish the optimal dosage of nanoparticles and observe the possibility to compensate the negative effect on workability by application of other admixtures, such as silica fume, fly ash, or superplasticizers. The researchers [39] established that optimal dosage of nanosilica should be less than 2% to reach the good workability of fresh mortar. The research [40] presents the increase in yield stress and viscosity of cement pastes modified by graphene oxide nanosheets.

The huge interest of researchers is paid to the modification of cement composites by carbon nanotubes (CNT) of different types. In most cases, CNT are introduced in the cement systems in dispersion form. The dispersant, type of homogenizer, and its intensity are the crucial issues in preparation of CNT dispersion. Reference [41] demonstrates the reduction in fluidity of fresh mixture modified by CNT. The authors of research studies [41–43] highlight the necessity to investigate the influence of the dispersant in combination with CNT when rheological properties of cement systems are evaluated. The authors of research [44] identified the dependence between ultrasonication energy, used in the preparation of CNT dispersion, and workability of nanomodified cement paste. It should be taken in consideration that rheological properties of nanomodified

cement systems can be changed with changes of the binder system. Reference [45] shows the increase of plastic viscosity and yield stress in the cement mortar modified by CNT and decrease of them in fly-ash-blast furnace slag-cement mortar.

The current research is devoted to the homogenization of multiwalled carbon nanotubes (MWCNT) dispersion, methods of quality evaluation of dispersion, and the investigation of the rheological properties of nanomodified cement paste with and without polycarboxylate ether.

2. Experimental Program

2.1. Raw Materials. The Portland cement without mineral additives CEM I 42.5 R conforming to EN 197-1 was used as a binder. The mineral and chemical composition of the cement is presented in Table 1.

The physical and mechanical properties of the cement are listed in Table 2.

The particle size distribution of cement curve, determined by CILAS 1090, is presented in Figure 1. The operating principle of CILAS 1090 is based on laser diffraction of beams. The range of measured particles is between 0.04 and 2500 μm . The main content of particles of cement is from 1 to 80 μm in size. The fineness of cement measured by the Blaine testing methodology reaches 4000 cm^2/g specific surface value and the average value of cement particles size is 14.28 μm .

Potable water according to EN 1008 was used for preparation of cement pastes. The polycarboxylate ether of the MPEG type (PCE), used as plasticizing admixture for concrete, with specific gravity 1.100 g/cm^3 , pH up to 5 at 20°C, and dry content equal to 50.5% was applied in the research.

The MWCNT dispersion was prepared from the masterbatch “Graphistrength CW 2-45” produced by the company “Arkema” (France). The masterbatch contains 45 wt.% of MWCNT and 55 wt.% of carboxymethylcellulose (CMC). The MWCNT was characterized by filament length equal to 0.1–10 μm and diameter equal to 15–20 nm. The concentration of “Graphistrength CW 2-45” in the dispersion was equal to 1.0%.

2.2. MWCNT Dispersion and Its Characterization. The MWCNT dispersion (D) was prepared in the following way. The masterbatch “Graphistrength CW 2-45” was immersed in hot water with a temperature of about 75°C and stirred by standard mixer agitation of about 1000 rpm during 15 min. Subsequently, the dispersion was subjected to ultrasonication for a duration of 6 min. The ultrasonication was performed by using a Bandelin Sonopuls HD 3400 ultrasonic homogenizer (400 W, 20 kHz) with probe VS 200 T (\varnothing 25 mm, amplitude $-82 \mu\text{m}$).

The prepared MWCNT dispersion was characterized by pH, electrical conductivity tests, measurements of zeta potential and particle size analysis. Further measurements were performed for PCE solution with and without MWCNT as well. The pH test was performed by using the pH-meter Mettler-Toledo EL20 with limits of error ± 0.01 pH. The electrode with gel electrolyte was used. Electrical

conductivity was measured by using Mettler-Toledo EL30. The measurement range of it is 0.1 to 199.1 mS/cm with limits of error $\pm 0.5\%$. The electrode for medium to high conductivities (10 $\mu\text{S}/\text{cm}$, . . . , 500 mS/cm) was applied. Zeta potential measurements were performed using an electroacoustic spectrometer DT-300 (Dispersion Technology Inc.) in aqueous solution with pH 4.9–8.7 and at a temperature of 20°C. The particle size analysis of diluted MWCNT dispersion in the aqueous medium and polydispersity index was determined by using particle size and zeta potential analyzer DelsaNano C, Beckman Coulter. The resolution of

measurements is placed from 0.6 nm to 7 μm . Three measurements were carried out for each sample, and average particle diameter was calculated.

2.3. Preparation of Cement Pastes and Rheology Test. The compositions of tested cement pastes are presented in Table 3.

MWCNT dispersion was dissolved in potable water. Water together with MWCNT dispersion was added to the cement, and the cement paste was mixed for 180 s at high speed by using a mixer. Rheological properties of cement pastes were tested in different time periods after paste mixing: 5, 30, 60, and 120 min. The rheology tests were carried out at temperature $20 \pm 2^\circ\text{C}$.

The rotational rheometer Rheotest RN 4.1 with coaxial cylinders was used for rheological tests. The scheme of cylinder-measuring system of the rheometer is presented in Figure 2. The assembled measuring cup (1) with coupling is poured by cement paste (3) and fixed in the equipment stand. The rotating cylinder rotor (2) is placed inside the measuring cup (1) with a gap between them of about 1.5 mm and rotated during the test. The intrinsic friction of cement paste layers takes place between the measuring cup (1) and cylinder rotor (2). The testing data are written when the rotating cylinder rotor makes a turn due to its connection with the measuring scale. The applied rheometer enables to test cement pastes in different modes.

The shear rate mode described by the graph in Figure 3 was used in the current experiments. Shear rate ranged from 100.0 s^{-1} to 0.1 s^{-1} during testing time. Cement pastes after mixing between tests were placed in the plastic containers and carried in the laboratory conditions with temperature $20 \pm 2^\circ\text{C}$ and relative humidity not less than 65%. The cement pastes were premixed before the rheological test by hands using metallic scoop for 1 min.

The yield stress (t_0) and plastic viscosity (μ_{pl}) were determined in the course of linear approximation of flow curves (dependence between shear stress (τ) and shear rate (γ) in the range from 0.1 to 100 s^{-1} based on the Bingham model. The Bingham model is a more widely used model for description of flow behavior of cement systems, which is expressed by following equation:

$$\tau = \tau_0 + \mu_{\text{pl}} \cdot \gamma, \quad (1)$$

where τ , shear stress, Pa; t_0 , yield stress of the cement paste, Pa; μ_{pl} , plastic viscosity of the cement paste, Pa·s; γ , shear rate, s^{-1} .

However, in some cases, the modified form of the Bingham model or Herschel-Bulkley model is required for description of cement pastes with nonlinear character of flow. The nonlinearity of flow curves was observed for cement pastes in the course of the research. The appearance of nonlinear character of flow curves is linked with a shear-thinning or shear-thickening effect which is inherent for cement pastes in some cases, especially modified by different types of chemical admixtures [46].

In the course of the current research, the attempt to evaluate the shear-thinning (shear-thickening) effect was made. The shear-thinning (shear-thickening) effects of cement pastes, as property of cement paste to decrease (increase) the plastic viscosity with increase of shear stress were determined by the usage of the traditional Bingham model in the ranges of shear rate $20\text{--}40 \text{ s}^{-1}$ and $80\text{--}100 \text{ s}^{-1}$. The experimental flow curves were approximated in these ranges, and values of viscosity were obtained. Equation (2) was derived to calculate the value of shear-thinning (shear-thickening) effects within the specified range of shear rates as follows:

$$T = \frac{\mu_{\text{pl},20-40} - \mu_{\text{pl},80-100}}{\mu_{\text{pl},20-40}} \cdot 100\%, \quad (2)$$

where $\mu_{\text{pl},20-40}$, plastic viscosity of cement paste in interval $20\text{--}40 \text{ s}^{-1}$ (Pa·s) and $\mu_{\text{pl},80-100}$, plastic viscosity of cement paste in interval $80\text{--}100 \text{ s}^{-1}$ (Pa·s).

3. Results and Discussion

3.1. Investigation of MWCNT Dispersion Stability. The results of pH, electrical conductivity, zeta potential measurements for PCE aqueous solution, and MWCNT aqueous dispersion and their mixtures are presented in Table 4.

Addition of PCE to MWCNT dispersion led to the decrease of the pH level of the system. Meanwhile, the electrical conductivity of PCE and MWCNT dispersion mixture was slightly higher compared with those separate components. These changes can be attributed to the chemical composition of PCE and physical interactions between molecules of the plasticizer and MWCNT.

More attention should be paid to zeta potential measurements of MWCNT dispersion with and without plasticizers. Zeta potential is presented on the boundary of the adsorption and diffuse layer. Determination of zeta potential is more simple and quite accurate method to predict the stability of colloidal systems. The colloidal systems are more stable with higher zeta potential.

Figure 4 shows the scheme of appearance of zeta potential on the MWCNT surface. MWCNT and agglomerates of MWCNT can have the layer of the potential-determining ions on the surface in connection with their small sizes. The potential-determining ions form the adsorption layer which has the diffusion layer around.

In the course of the current research, the zeta potentials were up to 1.79 mV, -14.51 mV , -2.72 mV , respectively, for PCE, MWCNT dispersions without, and with PCE. The higher value of zeta potential in MWCNT dispersion in comparison with PCE and mixture with PCE and MWCNT can be explained by the large-specific surface area of MWCNT particles and the great adsorption value of liquid phase molecules (Figure 4). The MWCNT dispersion with zeta potential equal to -14.51 is quite stable; however, addition of PCE leads to decrease of zeta potential and reduce the stability of MWCNT, water and PCE system.

TABLE 3: Content of materials for 1 m³ in tested cement pastes.

Specimen	Cement (kg)	Water (kg)	W/C ratio	PCE (kg)	MWCNT (kg)	MWCNT dispersion (kg)

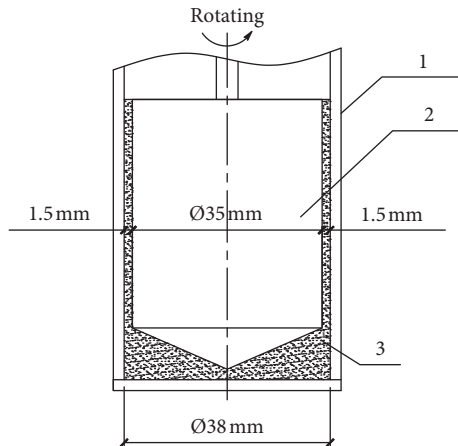

FIGURE 2: Scheme of cylinder-measuring system Rheotest RN 4.1.

In addition, the particle size analysis of dispersion is essential to make the conclusion about quality of dispersion. In the course of the current research, the particle size analysis, tested using an electroacoustic spectrometer, was performed for PCE solution, MWCNT dispersion, and their mixture. The results of particle size analysis are presented in Figure 5.

The particle size analysis of PCE solution revealed that the size of the derivatives in the sample ranged from 3 to 65 nm and the average diameter of polymer particles was about 31.5 nm. The dimension of MWCNT dispersion particles varied from 119 to 1070 nm with the average size up to 397.4 nm. The mixture of PCE and MWCNT dispersion was yielded as the sample with particle size distribution similar to that for MWCNT dispersion. Moreover, the typical peaks for PCE were not apparent, and little content of particles with dimensions up to 5 nm was obtained. The presence of modified particles in the range from 138 to 1000 nm with an average particle diameter up to 354.7 nm is caused by interactions of PCE molecules and MWCNT in mixture. The polydispersity index presents the deviation of particle size in dispersion from the average value. Addition of MWCNT dispersion to PCE reduces the polydispersity index from 0.344 to 0.197 which points out on better distribution of particles (Table 4). The zeta potential measurements and particle size analysis revealed that MWCNT dispersion without introduction of PCE possesses the better stability with zeta

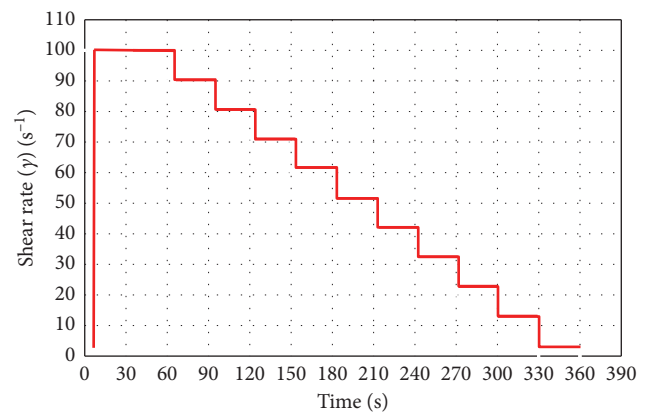

FIGURE 3: Shear rate mode of rheological test.

potential up to -14.51 and average particle size diameter of 397.4 nm. The applied PCE decreases the zeta potential value up to -2.72 and decreases the stability of the system. The research on the modification of PCE can promote the achievement of a more stable system.

3.2. Flow Behavior of Nanomodified Cement Pastes with and without PCE. Figures 6 and 7 present the flow behavior of nanomodified cement pastes in different dosages of MWCNT dispersion after 5 and 120 min from mixing, respectively. The flow curves equations according to the Bingham model are written near the corresponding curves. The values of plastic viscosity and yield stress after 5 and 120 min of mixing based on experimental equations are presented in Table 5.

The equations of cement pastes flow behavior according to the Bingham model were derived and presented in Figure 6 together with flow curves of pastes with different dosages of MWCNT dispersion. The yield stress and plastic viscosity values for cement pastes with different dosages of MWCNT after 5 and 120 min after mixing were determined and are presented in Table 5.

The introduction of MWCNT dispersion changes the flow behavior of cement pastes. The increase of shear stress and plastic viscosity of nanomodified cement pastes is observed in Figure 6 in the range of shear rate from 0.1 to 100 s⁻¹ in 5 min after mixing. The maximum increase of shear stress was identified for cement paste modified by MWCNT dispersion in dosage 0.25% by weight of cement.

TABLE 4: Characteristics of the samples.

Property	Polycarboxylate ether	MWCNT dispersion	Polycarboxylate ether + MWCNT dispersion
pH	5.00	8.67	4.91
Electrical conductivity (mS/cm)	3.12	3.32	3.55
Average diameter (nm)	31.5	397.4	354.7
Zeta potential (mV)	1.79	-14.51	-2.72
Polydispersity index	0.344	0.186	0.197

FIGURE 4: Zeta potential on the MWCNT surface.

The shear-thinning behavior takes place in the course of modification of cement paste by MWCNT dispersion. At the same time, as it is seen in Figure 7, shear stress and plastic viscosity were not changed for nanomodified cement pastes in the range of shear rate from 0.1 to 100 s^{-1} after 120 min of mixing. In other words, the plasticizing effect of MWCNT dispersion does not remain during the time due to physical-chemical processes in cement paste.

Figures 8 and 9 present the flow behavior of nano-modified cement pastes with PCE in different dosages in range from 0.125 to 0.5% by weight of cement in 5 and 120 min after mixing, respectively. The flow curve equations according to the Bingham model are written near the corresponding curves. The values of plastic viscosity and yield stress after 5 and 120 min of mixing based on experimental equations for cement pastes with PCE without and with MWCNT dispersion are presented in Table 6.

Plastic viscosity decreases slightly for cement pastes modified by PCE and MWCNT dispersion after 5 min of mixing in comparison with the sample modified only by PCE. The nanomodified cement pastes with PCE show the shear-thickening character of flow. As it is observed in Figure 9, the plasticizing effect remains on the same level during the 120 min after mixing of cement pastes.

Thus, modification of cement pastes by MWCNT dispersion demonstrates the shear-thinning behavior and the plasticizing effect after 5 min of mixing, which disappears after 120 min.

FIGURE 5: The particle size distribution by intensity of PCE solution (a), MWCNT dispersion (b), and PCE + MWCNT dispersion (c).

Cement pastes modified by MWCNT dispersion with PCE present the shear-thickening behavior and retain the plasticizing effect during the 120 min.

3.3. Plastic Viscosity and Yield Stress of Nanomodified Cement Pastes with and without PCE. Based on linear approximation and processing the experimental flow curves by the Bingham model, the dimensions of yield stress and plastic viscosity were obtained. The variation of yield stress and plastic viscosity were calculated based on the data presented in Tables 5 and 6.

Figure 10 presents the variation of yield stress and plastic viscosity of nanomodified cement paste in comparison with the reference sample without MWCNT dispersion after 5 min of mixing. The yield stress of nanomodified cement pastes decreases in the range from 15 to 30% in comparison with the reference sample without admixture. The maximum decrease in yield stress by 30.7% is observed for cement paste modified by MWCNT dispersion in dosage 0.25% by weight of cement.

The plastic viscosity increases in the range from 9 to 30% for nanomodified cement pastes in comparison with the reference sample. The maximum increase of plastic viscosity by 29.59% was established for cement pastes with MWCNT dispersion in the dosage 0.25% by weight of cement.

The data about variation of yield stress and plastic viscosity of cement pastes modified by MWCNT dispersion and PCE are presented in Figure 11. The usage of PCE with and without MWCNT dispersion leads to decrease of yield stresses of modified cement pastes up to 0 Pa.

The viscosity of nanomodified cement pastes with PCE decreases in the range from 2 to 9% in comparison with

FIGURE 6: Flow curves of nanomodified cement pastes after 5 min of mixing.

FIGURE 7: Flow curves of nanomodified cement pastes after 120 min of mixing.

TABLE 5: Values of plastic viscosity and yield stress for nanomodified cement pastes.

Dosage of MWCNT dispersion (%)	After 5 min		After 120 min	
	Yield stress (Pa)	Plastic viscosity, (Pa·s)	Yield stress (Pa)	Plastic viscosity (Pa·s)
0	13.90	1.433	12.22	2.507
0.125	11.71	1.569	5.934	2.568
0.25	11.05	1.707	10.76	2.561
0.5	9.636	1.857	10.95	2.536

reference samples modified only by PCE. The maximum decrease of plastic viscosity by 9.90% was identified for cement paste with PCE and MWCNT dispersion in the dosage 0.5% by weight of cement.

The results presented in Figures 12 and 13 describe the changes of plastic viscosity during the testing time.

The plastic viscosity of cement pastes tested after 120 min increases approximately by 1.5 times for all specimens in comparison with viscosity of cement pastes tested after 5 min.

The plastic viscosity of cement pastes modified by PCE in combination with MWCNT dispersion remains the same within 120 min duration time (Figure 13).

Thus, modification of cement pastes by MWCNT dispersion leads to increase of viscosity and decrease of yield stress for cement pastes tested after 5 min. The increase of viscosity for cement pastes tested after 120 min did not observed.

The modification of cement pastes by PCE with and without MWCNT dispersion demonstrated the decrease of

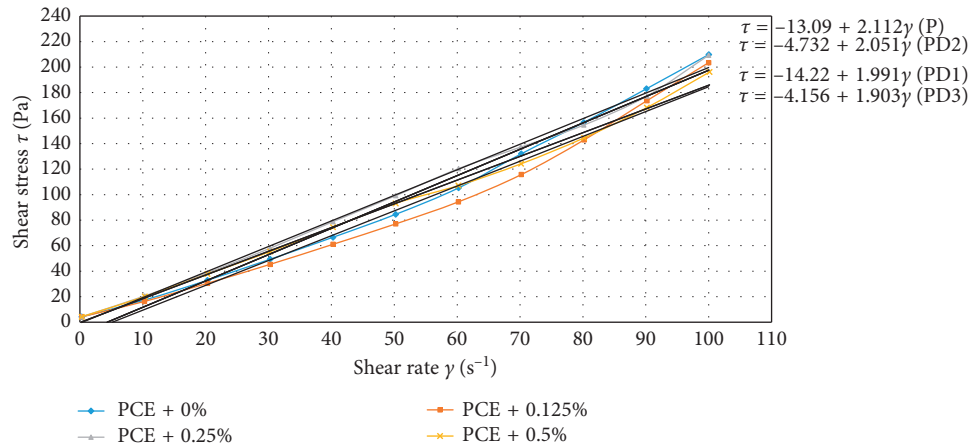

FIGURE 8: Flow curves of nanommodified cement pastes with PCE after 5 min of mixing.

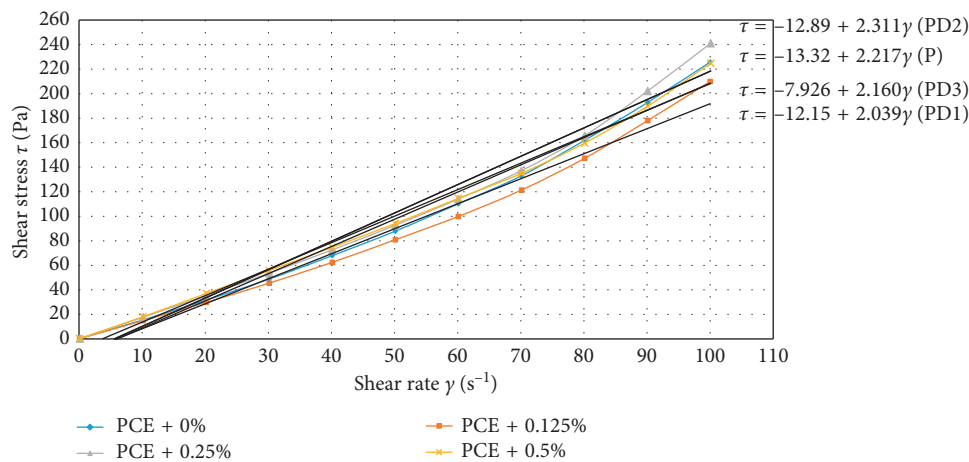

FIGURE 9: Flow curves of nanommodified cement pastes with PCE after 120 min of mixing.

TABLE 6: Values of plastic viscosity and yield stress for nanommodified cement pastes with PCE.

Dosage of PCE +MWCNT dispersion (%)	After 5 min		After 120 min	
	Yield stress (Pa)	Plastic viscosity, (Pa-s)	Yield stress (Pa)	Plastic viscosity (Pa-s)
PCE	0	2.112	0	2.217
PCE + 0.125	0	1.991	0	2.039
PCE + 0.25	0	2.051	0	2.311
PCE + 0.5	0	1.903	0	2.160

yield stress till 0 Pa and decrease of plastic viscosity. The plasticizing effect is remained during 120 min.

3.4. Shear-Thinning and Shear-Thickening Behavior of Nanommodified Cement Pastes. The reference cement paste and cement pastes modified by different dosages of MWCNT dispersion demonstrate the shear-thinning behavior (Figure 14), which remains within 120 min duration time of mixing. The maximum appearance of shear-thinning behavior by 20.9% was established for cement paste modified

with 0.25% of MWCNT dispersion by weight of cement after 120 min of mixing.

The introduction of PCE changes the shear-thinning behavior of cement pastes on shear-thickening behavior. The shear-thickening properties remains within 120 min duration time of mixing.

As it can be seen in Figure 15, the shear-thickening effect for PCE was 58.7% and 76.5% after 5 and 120 min of mixing, respectively. The decrease of shear-thickening effect is necessary for concrete technology. The addition of MWCNT dispersion to PCE enables to decrease shear-

FIGURE 12: Variation of plastic viscosity of nanommodified cement pastes within 120 min duration.

thickening effect. The optimal results were obtained for cement paste with PCE and MWCNT dispersion in the dosage of 0.5% by weight of cement. The shear-thickening effect was decreased by 18.1% and 3.8% for 5 and 120 min after mixing, respectively, in comparison with cement paste with PCE.

FIGURE 13: Variation of plastic viscosity of nanommodified cement pastes with PCE within 120 min duration.

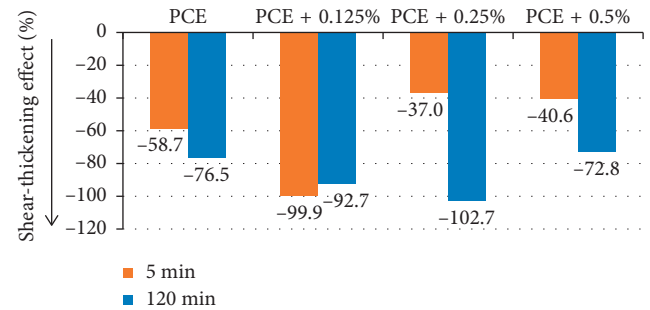

FIGURE 15: Shear-thickening behavior of nanommodified cement pastes with PCE within 5 and 120 min duration.

Thus, the cement pastes with and without MWCNT dispersion demonstrated the shear-thinning behavior; however, it was noticed that MWCNT dispersion does not influence significantly on appearance of this behavior. The shear-thinning behavior remains during 120 min of testing. The application of PCE leads to shear-thickening behavior of cement paste, which remains for 120 min after mixing. The introduction of MWCNT enables to decrease the shear-thickening effect.

3.5. Mechanism of Interactions between Particles and Its Influence on Rheology of Cement Paste. The rheological parameters of cement pastes are determined by parameters of solid particles and their interactions in the mixture. The

FIGURE 16: Mechanism of interaction of cement particles. (a) Without PCE. (b) With PCE. (c) With PCE and MWCNT dispersion.

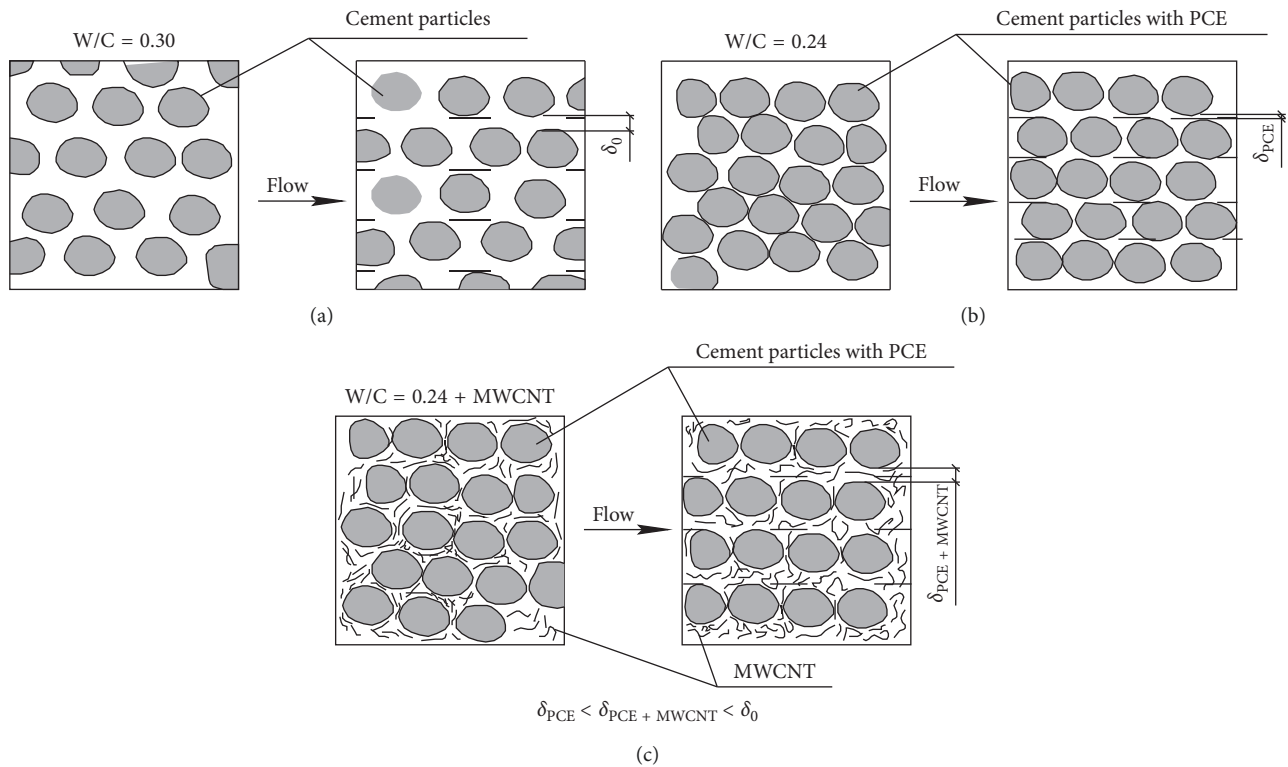

FIGURE 17: Flow behavior of cement pastes: (a) Without PCE. (b) With PCE. (c) With PCE and MWCNT dispersion.

attempts to find the dependence between rheological parameters and particle interactions were made in some rheological models. For instance, the Yodel model introduces the interparticle force parameter which depends on van der Waals attractive forces and electrostatic and steric interactions [47, 48].

It should be noted that interactions between cement particles are determined by water-cement ratio as well. In the course of the current research, the cement pastes with water to cement ratio equal to 0.30 were tested; the introduction of PCE in dosage 0.6% by weight of cement led to the decrease of water to cement ratio from 0.3 to 0.24 for the same consistency of cement paste. The reduction of the

amount of water in cement pastes leads to the decrease of spaces between cement grains and increase of shear-thickening effect in cement paste. The application of plasticizer allows to reach the cement pastes with equal consistency, reduce liquid phase, and reach low distance between cement particles. The mechanisms of interactions between cement particles in different conditions are presented in Figure 16.

As it is observed in Section 3.4, cement pastes can present the shear-thinning and shear-thickening behavior under mechanical action. Figure 17 shows the scheme of flow behavior of cement paste without PCE, with PCE, and with combined addition of MWCNT dispersion and PCE.

The properties of particles and interaction forces between them play the important role in this case as well.

The modification of cement pastes by PCE leads to the decrease of yield stress and plastic viscosity which are explained by electrostatic and steric forces in cement paste.

The cement pastes with MWCNT dispersion subjected to mechanical action showed the shear-thinning effect which can be explained by changes in volume distribution of cement particles and the increase of space between them.

The introduction of MWCNT dispersion in the cement system with PCE slightly increases the plasticizing effect. This fact can be explained by the steric effect and the increase of thickness of liquid phase between layers of cement paste.

The cement pastes modified by PCE with and without MWCNT dispersion demonstrated the shear-thickening behavior, which is linked with the decrease of the thickness of the liquid phase between layers in cement paste (Figure 17(c)).

Further investigation and formation of rheological models depending on the properties of particles and their interactions are required. The application of plasticizers has a great perspective in managing the rheological properties of cement pastes with and without nanoparticles.

4. Conclusions

The following conclusions are drawn in this study:

- (1) The MWCNT dispersion for modification of cement pastes with average particle diameter up to 397 nm and zeta potential up to -14.5 was obtained in the course of the research. The duration of ultrasonication about 6 min and the power equal to 400 W were established as optimal parameters of nano-dispersion homogenization.
- (2) The decrease of zeta potential from -14.5 up to -2.72 and the reduction of stability were obtained with addition of PCE to MWCNT dispersion. The modification of PCE can promote the achievement of the more stable system.
- (3) The modification of cement pastes by MWCNT dispersion presented the plasticizing effect for cement pastes tested in 5 min after mixing, which did not remain after 120 min of mixing. The modification of cement pastes by PCE with and without MWCNT dispersion leads to storage of plasticizing effect during 120 min after mixing.
- (4) The modification of cement pastes by MWCNT dispersion enables the decrease of the yield stress. The maximum decrease in yield stress by 30.7% is observed for cement paste modified by MWCNT dispersion in dosage of 0.25% by weight of cement.

The complex application of PCE and MWCNT dispersion decreases the water demand by 20% and decreases yield stress till 0 Pa.

- (5) The maximum increase of plastic viscosity by 29.59% was established for cement pastes with addition of MWCNT dispersion in the dosage of 0.25% by weight of cement after 5 min of mixing. The difference in plastic viscosity is not significant for all cement pastes with different contents of MWCNT tested in 120 min after mixing. The plastic viscosity of nanomodified cement pastes tested after 120 min increases approximately by 1.5 times for all specimens in comparison with viscosity of cement pastes tested in 5 min after mixing.
- (6) The cement pastes with MWCNT dispersion showed the shear-thinning behavior, which remains within 120 min duration time after mixing. The shear-thinning effect by 21% was established for cement paste modified with 0.25% of MWCNT dispersion by weight of cement. MWCNT effects marginally on the shear-thinning behavior of cement pastes in comparison with cement paste without MWCNT.
- (7) The addition of PCE change the shear-thinning behavior of cement pastes on shear-thickening behavior, which remains in 120 min after mixing. The addition of MWCNT dispersion to PCE enables to decrease shear-thickening effect. The optimal results were obtained for cement paste with PCE and MWCNT dispersion in the dosage of 0.5% by weight of cement. The shear-thickening effect was decreased by 18.1% and 3.8% for 5 and 120 min after mixing in comparison with cement paste without MWCNT.
